### Abstracts

The multi-hop routing in wireless sensor networks (WSNs) offers little protection against identity deception through replaying routing information. An adversary can exploit this defect to launch various harmful or even devastating attacks against the routing protocols, including sinkhole attacks, wormhole attacks and Sybil attacks. The situation is further aggravated by mobile and harsh network conditions. Traditional cryptographic techniques or efforts at developing trust-aware routing protocols do not effectively address this severe problem. To secure the WSNs against adversaries misdirecting the multi-hop routing, we have design and implemented TARF, a robust trust-aware routing framework for dynamic WSNs. Without tight time synchronization or known geographic information, TARF provides trustworthy and energy-efficient route. Most importantly, TARF proves effective against those harmful attacks developed out of identity deception; the resilience of TARF is verified through extensive evaluation with both simulation and empirical experiments on large-scale WSNs under various scenarios including mobile and RF-shielding network conditions.

Keywords: CTP - Collection Tree Routing Protocol, WSN - Wireless Sensor Network, TARF - Trust Aware Routing Framework.

### Introduction

Wireless sensor networks (WSNs) mainly supports military applications and forest fire monitoring. A WSN comprises battery-powered sensor nodes with extremely limited processing capabilities. With a narrow radio communication range, a sensor node wirelessly sends Wireless sensor networks (WSNs). With a narrow radio communication range, a sensor node wirelessly sends messages to a base station via a multi-hop path. However, the multi-hop routing of WSNs often becomes the target of malicious attacks. An attacker may tamper nodes physically, create traffic collision with seemingly valid transmission, drop or misdirect messages in routes, or jam the communication channel by creating radio interference. This paper focuses on the kind of attacks in which adversaries misdirect network traffic by identity deception through replaying routing information. Based on identity deception, the adversary is capable of launching harmful and hard-to-detect attacks against routing, such as selective forwarding, wormhole attacks, sinkhole attacks and Sybil attacks.As a harmful and easy-to-implement type of attack, a malicious node simply replays all the outgoing routing packets from a valid node to forge the latter node's identity; the malicious node then uses this forged identity to participate in the network routing, thus disrupting the network traffic. Those routing packets, including their original headers, are replayed without any modification. it can collude with other malicious nodes to receive those routing packets and replay them somewhere far away from the original valid node, which is known as a wormhole attack. Since a node in a WSN usually relies solely on the packets received to know about the sender's identity, replaying routing packets allows the malicious node to forge the identity of this valid node. After "stealing" that valid identity, this malicious node is able to misdirect the network traffic. For instance, it may drop packets received, forward packets to another node not supposed to be in the routing path, or even form a transmission loop through which packets are passed among a few malicious nodes infinitely. Sinkhole attacks are another kind of attacks that can be launched after stealing a valid identity. In a sinkhole attack, a malicious node may claim itself to be a base station through replaying all the packets from a real base station. Such a fake base station could gather more than half the traffic, creating a "black hole". This same technique can be employed to conduct another strong form of attack - Sybil attack through replaying the routing information of multiple legitimate nodes, an attacker may present multiple identities to the network. Also, it is important to consider efficient energy use for battery- powered sensor nodes and the robustness of under topological changes as well as routing authentication and encryption. To protect WSNs from the harmful attacks exploiting the replay of routing information, we have designed and implemented a robust trust-aware routing framework, TARF, to secure routing solutions in wireless sensor networks. Based on

http://www.ijesrt.com

(C)International Journal of Engineering Sciences & Research Technology

the unique characteristics of resource-constrained WSNs, the design of TARF centers on *trustworthiness* and *energy efficiency* 

### **Design considerations**

Before elaborating the detailed design of TARF, we would like to clarify a few design considerations first, including certain assumptions in Section 2.1 and the goals in Section 2.3.

### Assumptions

We target secure routing for data collection tasks, which are one of the most fundamental functions of WSNs. In a data collection task, a sensor node sends its sampled data to a remote base station with the aid of other intermediate nodes, as shown in Figure 1. Though there could be more than one base station, our routing approach is not affected by the number of base stations; to simplify our discussion, we assume that there is only one base station. Additionally, to merely simplify the introduction of TARF, we assume no data aggregation is involved.

Fig.1.Multi-hop routing for data collection of a WSN

Nonetheless, our approach can still be applied to clusterbased WSNs with static clusters, where data are aggregated by clusters before being relayed. Clusterbased WSNs allows for the great savings of energy and band- width through aggregating data from children nodes and performing routing and transmission for children nodes. In a cluster-based WSN, the cluster headers themselves form a sub-network; after certain data reach a cluster header, the aggregated data will be routed to a base station only through such a subnetwork consisting of the cluster headers. Our framework can then be applied to this sub-network to achieve secure routing for cluster- based WSNs.

Finally, we assume a data packet has at least the following fields: the sender id, the sender sequence number, the next-hop node id (the receiver in this one-hop transmission), the source id (the node that initiates the data), and the source's sequence number. We insist that the source node's information should be included for the following reasons because that allows the base

station to track whether a data packet is delivered. It would cause too much overhead to transmit all the onehop information to the base station. Also, we assume the routing packet is sequenced.

### Authentication requirements

TARF requires that the packets are properly authenticated, especially the broadcast packets from the base station. The broadcast from the base station is asymmetrically authenticated so as to guarantee that an adversary is not able to manipulate a broadcast message from the base station. Importantly, with authenticated broadcast, even with the existence of attackers, TARF may use Trust Manager (Section 3.4) and the received broadcast packets for delivery information (Section 3.2.1) to choose trustworthy path By circumventing compromised nodes.

The base station broadcast packets which are asymmetrically authenticated. The asymmetric authentication of those broadcast packets from the base station is crucial to any successful secure routing protocol. It can be achieved through existing asymmetrically authenticated broadcast schemes that may require loose time synchronization. As an example, μTESLA achieves asymmetric authenticated broadcast through a symmetric cryptographic algorithm and a loose delay schedule to disclose the keys from a examples of asymmetric chain. Other key authenticated broadcast schemes requiring either loose or no time synchronization are found. Considering the great computation cost incurred by a strong asymmetric authentication scheme and the difficulty in key management, a regular packet other than a base station broadcast packet may only be moderately authenticated through existing symmetric schemes with a limited set of keys, such as the message authentication code provided byTinySec.

### Goals

TARF mainly guards a WSN against the attacks misdirecting the multi-hop routing, especially those based on identity theft through replaying the routing information. TARF aims to achieve the following desirable properties:

**High Throughput** : Throughput is defined as the ratio of the number of all data packets delivered to the base station to the number of all sampled data packets. In our evaluation, throughput at a moment is computed over the period from the beginning time (0) until that particular moment. Note that single-hop re-transmission may happen, and that duplicate packets are considered as one packet as far as throughput is concerned. Through- put reflects how efficiently the network is

http://www.ijesrt.com

ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

collecting and delivering data. Here we regard high *throughput* as one of our most important goals.

Energy Efficiency: Data transmission accounts for a major portion of the energy consumption. We evaluate energy efficiency by the average energy cost to successfully deliver a unit-sized data packet from a source node to the base station. Note that link-level retransmission should be given enough attention when considering energy cost since each re-transmission causes a noticeable increase in energy consumption. If every node in a WSN consumes approximately the same energy to transmit a unit-sized data packet, we can use another metric *hop-per-delivery* to evaluate energy efficiency. Under that assumption, the energy consumption depends on the number of hops, i.e. the number of one-hop transmissions occurring. To evaluate how efficiently energy is used, we can measure the average hops that each delivery of a data packet takes, abbreviated as hop-per-delivery.

*Scalability & Adaptability* : TARF should work well with WSNs of large magnitude under highly dynamic contexts. We will evaluate the scalability and adaptability of TARF through experiments with large-scale WSNs and under mobile and hash network conditions.

#### **Design of TARF**

TARF secures the multi-hop routing in WSNs against intruders misdirecting the multi-hop routing by evaluating the trustworthiness of neighboring nodes. It identifies such intruders by their low trustworthiness and routes data through paths circumventing those intruders to achieve satisfactory *throughput*. TARF is also energy- efficient, highly scalable, and well adaptable. Before introducing the detailed design, we first introduce several necessary notion here.

**Neighbor** For a node N, a neighbor (neighboring node) of N is a node that is reachable from N with one-hop wireless transmission.

**Trust level** For a node N, the trust level of a neighbor is a decimal number in [0, 1], representing N's opinion of that neighbor's level of trustworthiness. Specifically, the trust level of the neighbor is N's estimation of the probability that this neighbor correctly delivers data received to the base station. That trust level is denoted as T in this paper. **Energy cost** For a node N, the energy cost of a neighbor is the average energy cost to successfully deliver a unit-sized data packet with this neighbor as its next-hop node, from N to the base station. That energy cost is denoted as E in this paper.

#### Overview

For a TARF-enabled node N to route a data packet to the base station, N only needs to decide to which neighboring node it should forward the data packet

considering both the trustworthiness and the energy efficiency. Once the data packet is forwarded to that next-hop node, the remaining task to deliver the data to the base station is fully delegated to it, and N is totally unaware of what routing decision its next-hop node makes. N maintains a neighborhood table with trust level values and energy cost values for certain known neighbors. It is sometimes necessary to delete some neighbors' entries to keep the table size acceptable. The technique of maintaining a neighborhood table of a moderate size is employed by TARF. A broadcast message from the base station is flooded to the whole network.

In TARF, in addition to data packet transmission, there are two types of routing information that need to be exchanged: broadcast messages from the base station about data delivery and energy cost report messages from each node. Neither message needs acknowledgement. A broadcast message from the base station is flooded. The freshness of a broadcast message is checked through its field of source sequence number. The other type of exchanged routing information is the energy cost report message from each node.

For each node N in a WSN, to maintain such a neighborhood table with trust level values and energy cost values for certain known neighbors, two components, EnergyWatcher and TrustManager, run on the node (Figure 2). EnergyWatcher is responsible for recording the energy cost for each known neighbor, based on N's observation of one-hop transmission to reach its neighbors and the energy cost report from those neighbors. A compromised node may falsely report an extremely low energy cost to lure its neighbors into selecting this compromised node as their next-hop node; however, these TARF-enabled neighbors eventually abandon that compromised next-hop node based on its low trustworthiness as tracked by TrustManager. TrustManager is responsible for tracking trust level values of neighbors based on network loop discovery and broadcast messages from the base station about data delivery. Once N is able to decide its nexthop neighbor according to its neighborhood table, it sends out its energy report message: it broadcasts to all its neighbors its energy cost to deliver a packet from the node to the base station. The energy cost is computed as in Section 3.3 by EnergyWatcher. Such an energy cost report also serves as the input of its receivers.

http://www.ijesrt.com

(C)International Journal of Engineering Sciences & Research Technology [586]

Fig. 2. Each node selects a next-hop node based on its neighborhood table, and broadcast its energy cost within its neighborhood. To maintain this neighborhood table, *Energy- Watcher* and *TrustManager* on the node keep track of related events (on the left) to record the energy cost and the trust level values of its neighbors.

### **Routing procedure**

TARF, as with many other routing protocols, runs as a periodic service. The length of that period determines how frequently routing information is exchanged and updated. At the beginning of each period, the base station broadcasts a message about data delivery during last period to the whole network consisting of a few contiguous packets (one packet may not hold all the information). Each such packet has a field to indicate how many packets are remaining to complete the broadcast of the current message. The completion of the base station broadcast triggers the exchange of energy report in this new period. Whenever a node receives such a broadcast message from the base station, it knows that the most recent period has ended and a new period has just started. No tight time synchronization is required for a node to keep track of the beginning or ending of a period. During each period, the EnergyWatcher on a node monitors energy consumption of one-hop transmission to its neighbors and processes energy cost reports from those neighbors to maintain energy cost entries in its neighborhood table; its TrustManager also keeps track of network loops and processes broadcast messages from the base station about data delivery to maintain trust level entries in its neighborhood table.

To maintain the stability of its routing path, a node may retain the same next-hop node until the next fresh broadcast message from the base station occurs. Meanwhile, to reduce traffic, its energy cost report could be configured to not occur again until the next fresh broadcast message from the base station. If a node does not change its next-hop node selection until the next broadcast message from the base station, that guarantees all paths to be loop-free, as can be deducted

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

from the procedure of next-hop node selection. However, as noted in our experiments, that would lead to slow improvement in routing paths. Therefore, we allow a node to change its next-hop selection in a period when its current next-hop node performs the task of receiving and delivering data poorly.

Next, we introduce the structure and exchange of routing information as well as how nodes make routing decisions in TARF.

# Structure and Exchange of Routing Information

A broadcast message from the base station fits into at most a fixed small number of packets. Such a message consists of some pairs of <node id of a source node, an undelivered sequence interval [a, b] with a significant length>, <node id of a source node, minimal sequence number received in last period, maximum sequence number received in last period>, as well as several node id intervals of those without any delivery record in last period. To reduce overhead to an acceptable amount, our implementation selects only a limited number of such pairs to broadcast (Section 5.1) and proved effective (Section 5.3, 5.4). Roughly, the effectiveness can be explained as follows: the fact that an attacker attracts a great deal of traffic from many nodes often gets revealed by at least several of those nodes being deceived with a high likelihood. The undelivered sequence interval [a, b] is explained as follows: the base station searches the source sequence numbers received in last period, identifies which source sequence numbers for the source node with this id are missing, and chooses certain significant interval [a, b] of missing source sequence numbers as an undelivered sequence interval. For example, the base station may have all the source sequence numbers for the source node 2 as {109, 110, 111, 150, 151} in last period. Then [112, 149] is an undelivered sequence interval; [109, 151] is also recorded as the sequence boundary of delivered packets. Since the base station is usually connected to a powerful platform such as a desktop, a program can be developed on that powerful platform to assist in recording all the source sequence numbers and finding undelivered sequence intervals.

Accordingly, each node in the network stores a table of <node id of a source node, a forwarded sequence interval [a, b] with a significant length> about last period. The data packets with the source node and the sequence numbers falling in this forwarded sequence interval [a, b] have already been forwarded by this node. When the node receives a broadcast message about data delivery, its *TrustManager* will be able to identify

which data packets forwarded by this node are not delivered to the base station. Considering the overhead to store such a table, old entries will be deleted once the table is full.

Once a fresh broadcast message from the base station is received, a node immediately invalidates all the existing energy cost entries: it is ready to receive a new energy report from its neighbors and choose its new next-hop node afterwards. Also, it is going to select a node either after a timeout is reached or after it has received an energy cost report from some highly trusted candidates with acceptable energy cost. A node immediately broadcasts its energy cost to its neighbors only after it has selected a new next-hop node. That energy cost is computed by its EnergyWatcher (see Section 3.3). A natural question is which node starts reporting its energy cost first. For that, note that when the base station is sending a broadcast message, a side effect is that its neighbors receiving that message will also regard this as an energy report: the base station needs 0 amount of energy to reach itself. As long as the original base station is faithful, it will be viewed as a trustworthy candidate by TrustManager on the neighbors of the base station. Therefore, those neighbors will be the first nodes to decide their next-hop node, which is the base station; they will start reporting their energy cost once that decision is made.

#### **Route Selection**

Now, we introduce how TARF decides routes in a WSN. Each node N relies on its neighborhood table to select an optimal route, considering both energy consumption and reliability. TARF makes good efforts in excluding those nodes that misdirect traffic by exploiting the replay of routing information.

For a node N to select a route for delivering data to the base station, N will select an optimal next-hop node from its neighbors based on trust level and energy cost and forward the data to the chosen next-hop node immediately. The neighbors with trust levels below a certain threshold will be excluded from being considered as candidates. Among the remaining known neighbors, N will select its next-hop node through evaluating each neighbor b based on a trade-off between  $T_{Nb}$  and  $E_{Nb}$ , with  $E_{Nb}$  and  $T_{Nb}$  being b's energy cost and trust level value in the neighborhood table respectively. Basically, E<sub>Nb</sub> reflects the energy cost of delivering a packet to the base station from N assuming that all the nodes in the route are honest;  $1/T_{Nb}$ approximately reflects the number of the needed attempts to send a packet from N to the base station via multiple hops before such an attempt succeeds,

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

considering the trust level of b. Thus, E<sub>Nb</sub> / T<sub>Nb</sub> combines the trustworthiness and energy cost. However, the metric  $E_{Nb}$  /  $T_{Nb}$  suffers from the fact that an adversary may falsely reports extremely low energy cost to attract traffic and thus resulting in a low value of  $E_{Nb}$  /  $T_{Nb}$  even with a low TNb. Therefore, TARF prefers nodes with significantly higher trust values; this preference of trustworthiness effectively protects the network from an adversary who forges the identity of an attractive node such as a base station. For deciding the next-hop node, a specific trade-off between  $T_{Nb}$  and  $E_{Nb}$   $T_{Nb}$  is demonstrated in Figure 5 (see Section 5.2). Observe that in an ideal misbehavior-free environment, all nodes are absolutely faithful, and each node will choose a neighbor through which the routing path is optimized in terms of energy; thus, an energy-driven route is achieved.

#### **Energy Watcher**

Here we describe how a node N's EnergyWatcher computes the energy cost ENb for its neighbor b in N's neighborhood table and how N decides its own energy cost E<sub>N</sub>. Before going further, we will clarify some notations. E<sub>Nb</sub> mentioned is the average energy cost of successfully delivering a unit-sized data packet from N to the base station, with b as N's next-hop node being responsible for the remaining route. Here, one-hop retransmission may occur until the acknowledgement is received or the number of re-transmissions reaches a certain threshold. The cost caused by one-hop retransmissions should be included when computing E<sub>Nb</sub>. Suppose N decides that A should be its next-hop node after comparing energy cost and trust level. Then N's energy cost is  $E_N = E_{NA}$ . Denote  $E_N \rightarrow b$  as the average energy cost of successfully delivering a data packet from N to its neighbor b with one hop. Note that the re- transmission cost needs to be considered. With the above notations, it is straightforward to establish the following

relation:  $E_{Nb} = E_N \rightarrow b + E_b$ 

Since each known neighbor b of N is supposed to broadcast its own energy cost Eb to N, to compute  $E_{Nb}$ , N still needs to know the value  $EN \rightarrow b$ , i.e., the average energy cost of successfully delivering a data packet from N to its neighbor b with one hop. For that, assuming that the endings (being acknowledged or not) of one- hop transmissions from N to b are independent with the same probability P<sub>succ</sub> of being acknowledged, we first compute the average number of one-hop sendings needed before the acknowledgement is received as follows:

 $\infty$  X i= 1 Psucc  $\cdot$  (1 – Psucc)<sup>i=1</sup> = 1 / Psucc

http://www.ijesrt.com

(C)International Journal of Engineering Sciences & Research Technology [588]

Denote Eunit as the energy cost for node N to send a unit-sized data packet once regardless of whether it is received or not. Then we have

#### ENb =Eunit/ Psucc+ Eb

The remaining job for computing ENb is to get the probability Psucc that a one-hop transmission is acknowledged. Considering the variable wireless connection among wireless sensor nodes, we do not use the simplistic averaging method to compute Psucc. Instead, after each transmission from N to b, N's EnergyWatcher will update Psuce based on whether that transmission is acknowledged or not with a weighted averaging technique. We use a binary variable Ack to record the result of current transmission: 1 if an acknowledgement is received; otherwise, 0. Given Ack and the last probability value of an acknowledged transmission P old suce, an intuitive way is to use a simply weighted average of Ack and P oldsuce as the value of Pnew succ. That is what is essentially adopted in the aging mechanism. However, that method used against sleeper attacks still suffers periodic attacks. To solve this problem, we update the Psucc value using two different weights as in our previous work , a relatively big  $W_{degrade}$  $\in (0,1)$  and a relatively small  $W_{upgrade} \in (0,1)$  as follows:  $pnew \; succ = (1 - W_{degrade}) \times \quad {}_{Pold \; succ} + W_{degrade} \times Ack,$ if Ack = 0.

 $(1 - W_{upgrade}) \times Pold succ} + W_{upgrade} \times Ack, if Ack = 1$ .

The two parameters  $W_{degrade}$  and  $W_{upgrade}$  allow flexible application requirements.  $W_{degrade}$  and  $W_{upgrade}$  represent the extent to which upgraded and degraded performance are rewarded and penalized, respectively. If any fault and compromise is very likely to be associated with a high risk,  $W_{degrade}$  should be assigned a relatively high value to penalize fault and compromise relatively heavily; if a few positive transactions can't constitute evidence of good connectivity which requires many more positive transactions, then  $W_{upgrade}$  should be assigned a relatively low value.

#### **Trust manager**

A node N's TrustManager decides the trust level of each neighbor based on the following events: discovery of network loops, and broadcast from the base station about data delivery. For each neighbor b of N, TNb denotes the trust level of b in N's neighborhood table. At the beginning, each neighbor is given a neutral trust level 0.5. After any of those events occurs, the relevant neighbors' trust levels are updated. Note that many existing routing protocols have their own mechanisms to detect routing loops and to react accordingly. In that case, when integrating TARF into those protocols with anti-loop

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

mechanisms, TrustManager may solely depend on the broadcast from the base station to decide the trust level; we adopted such a policy when implementing TARF later (see Section 5). If anti-loop mechanisms are both enforced in the TARF component and the routing protocol that in- tegrates TARF, then the resulting hybrid protocol may overly react towards the discovery of loops. Though sophisticated loop-discovery methods exist in the currently developed protocols, they often rely on the comparison of specific routing cost to reject routes likely leading to loops [32].

To minimize the effort to integrate TARF and the existing protocol and to reduce the overhead, when an existing routing protocol does not provide any anti- loop mechanism, we adopt the following mechanism to detect routing loops. To detect loops, the TrustManager on N reuses the table of <node id of a source node, a forwarded sequence interval [a, b] with a significant length> (see Section 3.2) in last period. If N finds that a received data packet is already in that record table, not only will the packet be discarded, but the TrustManager on N also degrades its next-hop node's trust level. If that next-hop node is b, then Told Nb is the latest trust level value of b. We use a binary variable Loop to record the result of loop discovery: 0 if a loop is received; 1 otherwise. As in the update of energy cost, the new trust level of b is

 $\begin{array}{l} T_{new\,Nb} = & (1 - W_{degrade}) \times T_{old\,Nb} + W_{degrade} \times Loop, \, if \, Loop \\ = 0. \end{array}$ 

=  $(1 - W_{upgrade}) \times T_{old Nb} + W_{upgrade} \times Loop$ , if Loop = 1.

Once a loop has been detected by N for a few times so that the trust level of the next-hop node is too low. N will change its next-hop selection; thus, that loop is broken. Though N can not tell which node should be held responsible for the occurrence of a loop, degrading its next-hop node's trust level gradually leads to the breaking of the loop. On the other hand, to detect the traffic misdirection by nodes exploiting the replay of routing information, TrustManager on compares N's stored table of <node id of a source node, forwarded sequence interval [a, b] with a significant length> recorded in last period with the broadcast messages from the base station about data delivery. It computes the ratio of the number of successfully delivered packets which are forwarded by this node to the number of those forwarded data packets, denoted as DeliveryRatio. Then N's TrustManager updates its next-hop node b's trust level as follows:

Tnew Nb =

 $(1 - W_{degrade}) \times T_{old Nb} + W_{degrade} \times DeliveryRatio, if DeliveryRatio < T_{old Nb.}$ 

 $(1 - W_{upgrade}) \times T_{old Nb} + W_{upgrade} \times DeliveryRatio, if DeliveryRatio >= T_{old Nb}.$

#### Analysis on EnergyWatcher and TrustManager

Now that a node N relies on its EnergyWatcher and TrustManager to select an optimal neighbor as its nexthop node, we would like to clarify a few important points on the design of EnergyWatcher and TrustManager. First, as described in Section 3.1, the energy cost report is the only information that a node is to passively receive and take as "fact". It appears that such acceptance of energy cost report could be a pitfall when an attacker or a compromised node forges false report of its energy cost. Note that the main interest of an attacker is to prevent data delivery rather than to trick a data packet into a less efficient route, considering the effort it takes to launch an attack. As far as an attack aiming at preventing data delivery is concerned, TARF well mitigates the effect of this pitfall through the operation of TrustManager. Note that the TrustManager on one node does not take any recommendation from the TrustManager on another node. If an attacker forges false energy report to form a false route, such intention will be defeated by TrustManager: when the TrustManager on one node finds out the many delivery failures from the broadcast messages of the base station, it degrades the trust level of its current next-hop node; when that trust level goes below certain threshold, it causes the node to switch to a more promising next- hop node. Second, TrustManager identities the low trustworthiness of various attackers misdirecting the multi-hop routing, especially those exploiting the replay of routing information. It is noteworthy that TrustManager does not distinguish whether an error or an attack occurs to the next-hop node or other succeeding nodes in the route. It seems unfair that TrustManager downgrades the trust level of an honest next-hop node while the attack occurs somewhere after that next-hop node in the route. Contrary to that belief, TrustManager significantly improves data delivery ratio in the existence of attack attempts of preventing data delivery. First of all, it is often difficult to identify an attacker who participates in the network using an id "stolen" from another legal node. For example, it is extremely difficult to detect a few attackers colluding to launch a combined wormhole and sinkhole attack . Additionally, despite the certain inevitable unfairness involved, TrustManager encourages a node to choose another route when its current route frequently fails to deliver data to the base station. Though only those legal neighboring nodes of an attacker might have correctly identified the adversary, our evaluation results indicate that the strategy of switching to a new route without identifying the attacker actually significantly improves the network performance, even with the existence of wormhole and sinkhole attacks. Fig 3 gives an example

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

to illustrate this point. In this example, node A, B, C and D are all honest nodes and not compromised. Node A has node B as its current next-hop node while node B has an attacker node as its next-hop node. The attacker drops every packet received and thus any data packet passing node A will not arrive at the base station. After a while, node A discovers that the data packets it forwarded did not get delivered. The TrustManager on node A starts to degrade the trust level of its current next-hop node B although node B is absolutely honest. Once that trust level becomes too low, node A decides to select node C as its new next-hop node. In this way node A identifies a better and successful route (A - C - D - base). In spite of the sacrifice of node B's trust level, the network performs better. Further, concerning the stability of routing path,

Fig. 3. An example to illustrate how TrustManager works.

once a valid node identifies a trustworthy honest neighbor as its next-hop node, it tends to keep that next-hop selection without considering other seemingly attractive nodes such as a fake base station. That tendency is caused by both the preference to maintain stable routes and the preference to highly trustable nodes. Finally, we would like to stress that TARF is designed to guard a WSN against the attacks misdirecting the multi-hop routing, especially those based on identity theft through replaying the routing information. Other types of attacks such as the denial-of-service (DoS) attacks are out of the discussion of this paper. For instance, we do not address the attacks of injecting into the network a number of data packets containing false sensing data but authenticated (possibly through hacking). That type of attacks aim to exhaust the network resource instead of misdirecting the routing. However, if the attacker intends to periodically inject a few routing packets to cause wrong route, such attacks can still be defended by TARF throughTrustManager.

#### Simulation

In our experiments, initially, 35 nodes are randomly distributed within a 300\*300 rectangular area, with unreliable wireless transmission. All the nodes have the same power level and the same maximal transmission range of 100m. Each node samples 6 times in every period; the timing gap between every two consecutive samplings of the same node is equivalent. We simulate the sensor network in 1440 consecutive periods.

Regarding the network topology, we set up three types of network topologies. The first type is the static-location case under which all nodes stand still. The second type is a customized group-motion-with-noise case based on Reference Point Group Mobility (RPGM) model that mimics the behavior of a set of nodes moving in one or more groups . The last type of dynamic network incorporated in the experiments is the addition of scattered RF-shielded areas to the afore mentioned group-motion-with-noise case.

The performance of TARF is compared to that of a link connectivity-based routing protocol. With the Link-connectivity protocol, each node selects its next-hop node among its neighborhood table according to an link estimator based on exponentially weighted moving average (EWMA). The simulation results show, in the presence of misbehaviors, the throughput in TARF is often much higher than that in Link-connectivity; the hop-per- delivery in the Link-connectivity protocol is generally at least comparable to that in TARF.

Both protocols are evaluated under three common types of attacks: (1) a certain node forges the identity of the based station by replaying broadcast messages, also known as the sinkhole attack; (2) a set of nodes colludes to form a forwarding loop; and (3) a set of nodes drops received data packets. These experiments were conducted in the static case, the group-motion-withnoise case, and the addition of RF-shielded areas to the group-motion-with-noise case separately. Generally, under these common attacks, TARF produces a substantial improvement over Link-connectivity in terms of data collection and energy efficiency. Further, we have evaluated TARF under more severe attacks: multiple moving fake bases and multiple Sybil attackers. As before, the experiments are conducted under all the three types of network topology. Under these two types of most severe attacks which almost devastates the Linkconnectivity protocol, TARF succeeds in achieving a steady improvement over the Link-connectivity protocol.

### **TrustManager implementation details**

The TrustManager component in TARF is wrapped into an independent TinyOS configuration named TrustManagerC. TrustManagerC uses a dedicated logic channel for communication and runs as a periodic service with a configurable period, thus not interfering with the application code. Though it is possible to implement TARF with a period always synchronized with the routing protocol's period, that would cause much intrusion into the source code of the routing protocol. The current TrustManagerC uses a period of 30 seconds; for specific

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

applications, by modifying a certain header file, the period length may be re-configured to reflect the sensing frequency, the energy efficiency and trustworthiness requirement. TrustManagerC provides two inter- faces (see Figure 4), TrustControl and Record, which are implemented in other modules. The TrustControl interface provides the commands to enable and disable the trust evaluation, while the Record interface provides the commands for a root, i.e., a base station, to add delivered message record, for a non-root node to add forwarded message record, and for a node to retrieve the trust level of any neighboring node. The implementation on a root node differs from that on a non-root node: a root node stores the information of messages received (delivered) during the current period into a record table and broadcast delivery failure record; a non-root node stores the information of forwarded messages during the current period also in a record table and compute the trust of its neighbors based on that and the broadcast information. Noting that much implementation overhead for a root can always be transferred to a more powerful device connected to the root, it is reasonable to assume that the root would have great capability of processing and storage.

#### Fig. 4. TrustManager component.

A root broadcasts two types of delivery failure record: at most three packets of significant undelivered intervals for individual origins and at most two packets of the id's of the origins without any record in the current period. For each origin, at most three significant undelivered intervals are broadcast. For a non-root node, considering the processing and memory usage overhead, the record table keeps the forwarded message intervals for up to 20 source nodes, with up to 5 non-overlapped intervals for each individual origin. Our later experiments verify that such size limit of the table on a non-root node produces a resilient TARF with moderate overhead. The record table on a node keeps adding entries for new origins until it is full. With our current implementation, a valid trust value is an integer between 0 and 100, and any node is assigned an initial trust value of 50. The weigh

parameters are: wupgrade = 0.1, wdegrade = 0.3. The trust table of a non-root node keeps the trust level for up to 10 neighbors. Considering that an attacker may present multiple fake id's, the implementation evicts entries with a trust level close to the initial trust of any node. Such eviction policy is to ensure that the trust table remembers those neighbors with high trust and low trust; any other neighbor not in this table is deemed to have the initial trust value of 50.

### Incorporation of TARF into existing protocols

To demonstrate how this TARF implementation can be integrated into the existing protocols with the least effort, we incorporated TARF into a collection tree routing protocol (CTP). The CTP protocol is efficient, robust, and reliable in a network with highly dynamic link topology. It quantifies link quality estimation in order to choose a next-hop node. The software platform is TinyOS 2.x. To perform the integration, after proper interface wiring, invoke the TrustControl.start command to enable the trust evaluation: call the Record.addForwarded command for a non-root node to add forwarded record once a data packet has been forwarded; call the Record.addDelivered command for a root to add delivered record once a data packet has been received by the root. Finally, inside the CTP's task to update the routing path, call the Record.getTrust command to retrieve the trust level of each next-hop candidate; an algorithm taking trust into routing consideration is executed to decide the new next-hop neighbor.(See Figure 5).

Similar to the original CTP's implementation, the implementation of this new protocol decides the next-hop neighbor for a node with two steps (see Figure 5): Step 1 traverses the neighborhood table for an optimal candidate for the next hop; Step 2 decides whether to switch from the current next-hop node to the optimal candidate found. For Step 1, as in the CTP implementation, a node would not consider those links congested, likely to cause a loop, or having a poor quality lower than a certain threshold. This new implementation prefers those candidates with higher trust levels; in certain circumstances, regardless of the link quality, the rules deems a neighbor with a much higher trust level to be a better candidate (see Figure 5). The preference of highly trustable candidates is based on the following consideration: on the one hand, it creates the least chance for an adversary to misguide other nodes into a wrong routing path by forging the identity of an attractive node such as a root; on the other hand, forwarding data packets to a candidate with a low trust level would result in many unsuccessful link-level transmission attempts, thus leading to much re-

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

transmission and a potential waste of energy. When the network throughput becomes low and a node has a list of low-trust neighbors, the node will exclusively use the trust as the criterion to evaluate those neighbors for routing decisions. As show in Figure 5, it uses trust/cost as a criteria only when the candidate has a trust level above certain threshold. The reason is, the sole trust/cost criteria could be exploited by an adversary replaying the routing information from a base station and thus pretending to be an extremely attractive node. As for Step 2, compared to the CTP implementation, we add two more circumstances when a node decides to switch to the optimal candidate found at Step 1: that candidate has a higher trust level, or the current next-hop neighbor has a too low trust level.

#### **Empirical EvaluationonMotelab**

We evaluated the performance of TARF against a combined sinkhole and wormhole attack on Motelab at Harvard University. 184 TMote Sky sensor motes were deployed across many rooms at three floors in the department building (see Figure 6), with two to four motes in most rooms. Around 97 nodes functioned properly while the rest were either removed or disabled. Each mote has a 2.4GHz Chipcon CC2420 radio with an indoor range of approximately 100 meters. In Figure 6, the thin green lines indicate the direct (one-hop) wireless connection between motes. Certain wireless connection also exists between nodes from different floors.

Fig. 6. Connectivity map of Motelab (not including the interfloor connectivity), adapted from Motelab[Motelab].

We developed a simple data collection application in TinyOS 2.x that sends a data packet every five seconds to a base station node (root) via multi-hop. This application was executed on 91 functioning non-root nodes on Motelab. For comparison, we used CTP and the TARFenabled CTP implementation as the routing protocols for the data collection program separately. The TARFenabled CTP has a TARF period of 30 seconds. We conducted an attack with five fake base stations that formed a wormhole. As in Figure 6, whenever the base station sent out any packet, three fake base stations which overheard that packet replayed the complete packet without changing any content including the node id. Other fake base stations overhearing that replayed packet would also replay the same packet. Each fake base station essentially launched a sinkhole attack. Note that there is a distinction between such malicious replay and the forwarding when a well-behaved node receives a broadcast from the base station. When a well-behaved node forwards a broadcast packet from the base station, it will include its own id in the packet so that its receivers will not recognize the forwarder as a base station. We conducted the first experiment by uploading the program with the CTP protocol onto 91 motes (not including those 5 selected motes as fake bases in later experiments), and no attack was involved here. Then, in another experiment, in addition to programming those 91 motes with CTP, we also programmed the five fake base stations so that they stole the id the base station through replaying. In the last experiment, we programmed those 91 motes with the TARF-enabled CTP, and programmed the five fake base stations as in the second experiment. Each of our programs run for 30 minutes. As illustrated in Figure 7(a), the existence of the five wormhole attackers greatly degraded the performance of CTP: the number of the delivered data packets in the case of CTP with the five-node wormhole is no more than 14% that in the case of CTP without adversaries. The TARF-enabled CTP succeeded in bringing an immense improvement over CTP in the presence of the five-node wormhole,

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

almost doubling the throughput. That improvement did not show any sign of slowing down as time elapsed. The number of nodes from each floor that delivered at least one data packet in each six-minute sub-period is plotted in Figure 7(a), 7(b) and 7(c) separately. On each floor, without any adversary, at least 24 CTP nodes were able to find a successful route in each six minute. However, with the five fake base stations in the wormhole, the number of CTP nodes that could find a successful route goes down to 9 for the first floor; it decreases to no more than 4 for the second floor; as the worst impact, none of the nodes on the third floor ever found a successful route. A further look at the data showed that all the nine nodes from the first floor with successful delivery record were all close to the real base station. The CTP nodes relatively far away from the base station, such as those on the second and the third floor, had little luck in making good routing decisions. When TARF was enabled on each node, most nodes made correct routing decisions circumventing the attackers. That improvement can be verified by the fact that the number of the TARF- enabled nodes with successful delivery record under the threat of the wormhole is close to that of CTP nodes with no attackers, as shown in Figure 7(a), 7(b) and 7(c).

### Application: mobile target detection in the Pres- ence of an Anti-Detection Mechanism

To demonstrate how TARF can be applied in networked sensing systems, we developed a proof-of-concept resilient application of target detection. This application relies on a deployed wireless sensor network to detect a target that could move, and to deliver the detection events to a base station via multiple hops with the TARFenabled CTP protocol. For simplification, the target is a LEGO MINDSTORM NXT 2.0 vehicle robot equipped with a TelosB mote that sends out an AM(Active Message) packet every three seconds. A sensor node receiving such a packet from the target issues a detection report, which will be sent to the base station with the aforementioned TARF-enabled CTP protocol. The experiment is set up within a clear floor space of 90 by 40 inches with 15 TelosB motes (see Figure 8(a)). To make the multi-hop delivery necessary, the transmission power of all the Telosb motes except two fake base stations in the network is reduced through both software reduction and attenuator devices to within 30 inches. The target uses an anti-detection mechanism utilizing a fake base station close to the real base station, and another remote base station close to the target and mounted on another LEGO vehicle robot. The two fake base stations, with a transmission range of at least 100 feet, collude to form a wormhole: : the fake base station close to the base station replays all the packets from the base station

### ISSN: 2277-9655 Scientific Journal Impact Factor: 3.449 (ISRA), Impact Factor: 2.114

immediately; the remote fake base station, after receiving those packets, immediately replays it again.

(c) Second floor.

Fig. 7. Empirical comparison of CTP and TARF-enabled CTP on Motelab: (a) number of all delivered data packets since the beginning; number of nodes on (b) the first floor, (c) the second floor and (d) the third floor that delivered at least one data packet in sub-periods.

This anti- detection mechanism tricks some network nodes into sending their event reports into these fake base stations instead of the real base station. Though the fake base station close to the real base station is capable of cheating the whole network alone by itself with its powerful radio for a certain amount of time, it can be easily recognized by remote nodes as a poor next-hop candidate soon by most routing protocols based on link quality: that fake base station does not acknowledge the packets "sent" to it from remote nodes with a weak radio via a single hop since it can not really receive them. Thus, the anti- detection mechanism needs to create such a wormhole to replay the packets from the base station remotely.

The target node 14 and the fake base station 13 close to it move across the network along two parallel tracks of 22 inches back and forth (see Figure 8(b)); they travel on each forward or backward path of 22 inches in around 10 minutes. The experiment lasts 30 minutes. For comparison, three nodes 9, 10 and 11 programmed with the CTP protocol are paired with another three nodes 6, 7 and 8 programmed with the TARF-enabled CTP (see Figure 8(b)); each pair of nodes are physically placed close enough. All the other nodes, except for the fake base stations and the target node, are programmed with the TARF-enabled CTP. To fairly compare the performance between CTP and the TARF-enabled CTP, we now focus on the delivered detection reports originating from these three pairs of nodes: pair (9, 6), (10, 7) and (11, 8). For the timestamp of each detection report from these six nodes, we plot a corresponding symbol: a purple circle for the nodes with the TARF-enabled CTP; a black cross for the CTP nodes. The resulting detection report is visualized in Figure 9(a). Roughly, the TARF nodes report the existence of the target seven times as often as the CTP nodes do. More specifically, as shown in Figure 9(b), in the pair (9, 6), no report from CTP node 9 is delivered while 46 reports from TARF node 6 is delivered; in the pair (10, 7), no report from CTP node 10 is delivered while 80 reports from TARF node 7 is delivered; in the pair (11, 8), 40 reports from CTP node 11 is delivered while 167 reports from TARF node

(C)International Journal of Engineering Sciences & Research Technology [594] 8 is delivered. Taking into account the spatial proximity between each pair of nodes, the TARF-enabled CTP achieves an enormous improvement in target detection over the original CTP.

Fig. 8. Deployment of a TARF-enabled wireless sensor network to detect a moving target under the umbrella of two fake base stations in a *wormhole*.

Fig. 9. Comparison of CTP and the TARF-enabled CTP in detecting the moving target.

The demonstration of our TARF-based target detection application implies the significance of adopting a secure routing protocol in certain critical applications. The experimental results indicate that TARF greatly enhances the security of applications involving multihop data delivery.

### **Related work**

We discuss more related work here in addition to the introduction in Section 1. It is generally hard to protect WSNs from *wormhole* attacks, *sinkhole* attacks and *Sybil* attacks based on identity deception. The countermeasures often requires either tight time synchronization or known geographic information as a feedback-based secure routing protocol for WSNs, uses a statistics-based detection on a base station to discover potentially compromised nodes. But the claim that FBSR is resilient against *wormhole* and *Sybil* attacks is never evaluated or examined; the Keyed-OWHC-based authentication used by FBSR also causes considerable overhead. There also exists other work on trust-aware secure routing that is evaluated only through computer simulation.

There are certain existing secure routing solutions for WSNs based on trust and reputation management; however, they rarely address the "identity theft" exploiting the replay of routing information. Two such representative solutions are ATSR and TARP. Neither ATSR nor TARP offers protection against the identity deception through replaying routing information. ATSR is a location-based trust-aware routing solution for large WSNs. ATSR incorporates a distributed trust model utilizing both direct and indirect trust, geographical information as well as authentication to protect the WSNs from packet misforwarding, packet manipulation and acknowledgements spoofing. Another trust-aware routing protocol for WSNs is TARP, which exploits nodes' past routing behavior and link quality to determine efficient paths.

### Conclusions

We have designed and implemented TARF, a robust trust-aware routing framework for WSNs, to secure multi-hop routing in dynamic WSNs against harmful attackers exploiting the replay of routing information. TARF focuses on trustworthiness and energy efficiency, which are vital to the survival of a WSN in a hostile environment. With the idea of trust management, TARF enables a node to keep track of the trustworthiness of its neighbors and thus to select a reliable route. Our main contributions are listed as follows. (1) Unlike previous efforts at secure routing for WSNs, TARF effectively protects WSNs from severe attacks through replaying routing information; it requires neither tight time synchronization nor known geographic information. (2) The resilience and scalability of TARF is proved through both extensive simulation and empirical evaluation with large-scale WSNs; the evaluation involves both static and mobile settings, hostile network conditions, as well as strong attacks such as wormhole attacks and Sybil attacks. (3) We have implemented a ready-to-use TinyOS module of TARF with low overhead; as demonstrated in the paper, this TARF module can be integrated into existing routing protocols with the least effort, thus producing secure and efficient fully-functional protocols. (4) Finally, we demonstrate a proof-of-concept mobile target detection application that is built on top of TARF and is resilient in the presence of an anti-detection mechanism: that indicates the potential of TARF in WSN applications.
